Ballistic phonon studies in the lowest Landau level

School of Physics and Astronomy, University of Nottingham, Nottingham, NG7 2RD, UK

Abstract

We report time-resolved studies of ballistic phonon absorption in the fractional quantum Hall regime at Landau level filling factors of \( v = \frac{1}{3}, \frac{1}{5} \) and \( \frac{1}{2} \). The technique used can resolve the interaction of the two-dimensional electron system with LA and TA phonons and has been used to measure the temperature variation of the heat capacity of a single layer of electrons at \( v = \frac{1}{3} \). The energy gaps at \( v = \frac{1}{3} \) have also been measured and found to be in good agreement with theory. The roles of compressible and incompressible regions in the phonon absorption process are discussed. Angle resolved measurements at \( v = \frac{2}{5} \) are also in good agreement with theory. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

The fractional quantum Hall effect (FQHE) occurs due to the formation of a quantum liquid when the Landau level filling factor, \( v = \frac{r}{s} \), where \( r \) and \( s \) are integers and \( s \) is odd. When \( v = 1/s \) the wave function is accurately described by Laughlin’s variational wave function [1] and the low-lying collective excitations of the system, by the theory of Girvin et al. [2,3]. More generally, the collective excitation dispersion has been calculated by Kamilla et al. [4]. The most significant features of the excitations are the existence of a finite energy gap at low wave vectors, due to the incompressibility of the FQHE state, and a deep minimum in the energy, \( A^* \), of the excitations known as magnetorotons, close to the wave vector where the static structure factor of the liquid is a maximum. The experiments described here probe the interaction of acoustic phonons with these excitations and use the results to determine the temperature variation of the heat capacity of the 2DES at \( v = \frac{1}{3} \). The inter-action between longitudinal acoustic (LA) and transverse acoustic (TA) phonons and the two-dimensional electron system (2DES) have been resolved.

2. Experimental method

The detailed description of the experimental technique has been given elsewhere [5,6]. The samples used are single GaAs/AlGaAs heterojunctions grown on a 2 mm thick substrate. The 2DES ($n_s = 1.1 \times 10^{15} \text{ m}^{-2}$, mobility $=150 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$) is patterned into a meandering hall bar with a length-to-width ratio of around 260. This maximises the sensitivity to changes in longitudinal resistance. On sample A, the meander covers an area of $5 \text{ mm} \times 5 \text{ mm}$, whilst on sample B the area of the meander is $1 \text{ mm} \times 1 \text{ mm}$ to decrease the solid angle of the device as seen from the other side of the wafer. On the reverse of the wafer, thin film constantan heaters have been evaporated directly opposite the meander and at $45^\circ$ to it.

A voltage pulse (5–50 ns) is applied to the thin film heater causing it to emit a black body spectrum of phonons of known temperature [7]. The emitted phonons travel ballistically across the wafer and a small fraction are absorbed by the 2DES. This absorption process heats the 2DES causing a change in the longitudinal resistance. This resistance change is measured with a time resolution of approximately 30 ns by a signal averaging technique. By calibrating the meander resistance against substrate temperature in the absence of ballistic phonons, the transient electron temperature during the absorption of ballistic phonons can be found. A typical trace for the case of a heater at a $45^\circ$ to the meander in the [110] direction is shown in Fig. 1.

3. Ballistic phonon absorption at $\nu = \frac{1}{2}$

Previously, we have shown that at $\nu = \frac{1}{2}$, the fraction of incident phonon flux absorbed is reduced above a heater temperature of 1.4 K for the case when the heater is directly under the meander [5,6]. Along with other measurements, this suggests that the strength of the phonon interaction is limited by the finite thickness, $a_0$, of the 2DES which can be determined to be around $5 \pm 1 \text{ nm}$ from the phonon measurements. This is in agreement with the behaviour of two-dimensional systems at zero-magnetic field [8] and suggests a broad spectrum frequency absorption due to the creation of particle hole pairs until the perpendicular component of the phonon wave vector, $q_\perp$, exceeds $1/a_0$.

4. Ballistic phonon absorption at $\nu = \frac{1}{3}$

The fraction of acoustic phonons absorbed, $r_0$, at the magnetoroton energy, $\Delta^*$, will be approximately constant as long as $\exp(-\Delta^*/k_B T) \ll 1$. This means that the energy absorbed by the FQHE liquid from a pulse of non-equilibrium phonons,

$$\text{d}E = C(T) \text{d}T = r_0 P \tau,$$

where $P$ is the heater power, $\tau$ the pulse length, $C$ the 2DES heat capacity and $dT$, the temperature change of the 2DES. Keeping the heater temperature and pulse length constant, we vary the lattice temperature and as long as the temperature variation $dT \ll T$, a good estimate of the temperature variation of the heat capacity can be determined. Whilst a Schottky heat capacity is predicted [9], the heat capacity is found to vary as $C(T) = AT + BT^2$ (see Fig. 2). A density of states can be constructed from the heat
Fig. 2. Variation of the specific heat of the 2DES with temperature at \( v = \frac{1}{3} \). The solid line shows a fit taking into account only the \( T \) and \( T^7 \) terms in the Sommerfeld expansion of the specific heat. The inset sketches the composite fermion density of states at \( v = \frac{1}{3} \) as extracted from the specific heat data.

The specific heat capacity is plotted using the Sommerfeld construction (see Fig. 2). A possible explanation of the data is that the linear term in the heat capacity at low temperatures is due to compressible localised states whilst the higher power is the low-temperature tail of a Schottky-like heat capacity due to the incompressible FQHE liquid.

Initially the 2DES is at a low base temperature \( T_e(0) \) whilst the phonons are characterized by an effective temperature, \( T_h \). The 2DES is not uniform but consists of compressible islands within a percolating sea of incompressible electron liquid. Within the incompressible regions screening is very inefficient and the lowest lying excitations are the magnetorotons. In the compressible regions, the screening is metallic and relatively more efficient while the low lying density excitations (to which the phonons couple directly) are particle–hole pairs as in a normal metal. When the phonon pulse comes into contact with the 2DES particle–hole pairs are created in the compressible regions and magnetorotons in the incompressible regions. The relative efficiency of the screening in the compressible regions leads us to suppose that the coupling to the phonons will be relatively weak and that, for a sufficiently small coverage, the energy transfer will be dominated by magnetoroton creation in the incompressible regions. The expectation is that the excitations created by the absorption processes will then rapidly (on the timescale of the experiment) equilibrate leading to an increased electron temperature. The heat capacity of the compressible regions will be metallic \( \left( -a_c T_e \right) \) while that of the incompressible regions will be activated \( \left( -a_i \exp(-\Delta_k/kT_e) \right) \) so that the latter is negligible at a sufficiently low electron temperature. In other words, the rare high-energy phonons create magnetorotons in the incompressible fluid, these deposit their energy into the compressible regions which act as heat baths establishing a well-defined electron temperature. The longitudinal conductance is activated, \( \sigma_{xx} \sim \sigma_0 \exp(-\Delta/\kappa T_e) \), where \( \Delta \) is the energy gap for the creation of unbound Laughlin quasiparticles, so its measurement gives the electron temperature.

If the initial temperature of the lattice is maintained and the heater temperature varied for constant pulse length, the energy absorbed as a function of heater temperature can be calculated (Fig. 3). The results are consistent with phonon absorption across a well-defined energy gap. The energy gap obtained from the measurements is in good agreement with theoretical estimates of the magnetoroton gap \([2,3]\) and is unaffected by disorder in the sample. The energy

Fig. 3. Dependence of the energy absorbed by the 2DES on the heater temperature, \( T_h \). The solid line shows the fitted behaviour for the absorption across a magnetoroton gap, \( \Delta^* = 7 \pm 1 \) K. The energy absorbed varies as \( 1 / (\exp(-\Delta^*/kT_h) - 1) \).
Fig. 4. Total energy absorbed at \( v = \frac{1}{2} \) and \( \frac{1}{3} \) as a function of the pulse length. The lines represent the behaviour of a system coming into a dynamic equilibrium by emitting phonons on time scales of \( \tau = 70 \text{ ns} \) (\( v = \frac{1}{2} \)) and \( \tau = \infty \) (\( v = \frac{1}{3} \)), i.e. no equilibrium at all.

5. Angle-resolved experiments at \( v = \frac{2}{5} \)

At \( v = \frac{2}{5} \), we have observed ballistic phonon absorption in which the in-phonon wave vectors lie in a small range close to the wave vector at which the magnetoroton minimum is predicted (Fig. 1). The geometric range of angles subtended by the heater was from 30° to 60°. Experimentally, both absorption of both LA and TA phonons are observed. To calculate the range of in-plane wave vectors the effect of phonon anisotropy needs to be taken into account in the interaction, therefore here we present the results for the LA phonons only, as LA phonons are only weakly focused. For \( v = \frac{2}{5} \) we find that the magnetoroton energy gap for phonons with in-plane momenta, \( q \), in the range \( 0.4 < q l_0 < 0.75 \) is \( 0.025(3) e^2/4\pi \psi_0 l_0 \). This is in reasonable agreement (0.032(3) \( e^2/4\pi \psi_0 l_0 \)) with theoretical estimates [4] corrected for finite thickness effects [10].
